Cobalamins (Cbl; vitamin B₁₂ derivatives) are micronutrients essential for the synthesis of methylcobalamin (MeCbl) and adenosylcobalamin (AdoCbl), the respective cofactors for cytosolic methionine synthase (MS) and mitochondrial l-methylmalonyl-CoA mutase. Reduced Cbl cofactors in the catalytic cycles are sensitive to oxidative-stress-associated pathologies. Reduced Cbl reacts with O₂⁻ at rates approaching that of superoxide dismutase (SOD), suggesting a plausible mechanism for its anti-inflammatory properties. Elevated homocysteine (Hcy) is an independent risk factor for cardiovascular disease and endothelial dysfunction. Hcy increases O₂⁻ levels in human aortic endothelial cells (HAEc). Here, we explore the protective effects of Cbl in HAEc exposed to various O₂⁻ sources, including increased Hcy levels. Hcy increased O₂⁻ levels (1.6-fold) in HAEc, concomitant with a 20% reduction in cell viability and a 1.5-fold increase in apoptotic death. Pretreatment of HAEc with physiologically relevant concentrations of cyanocobalamin (CNCbl) (10–50 nM) prevented Hcy-induced increases in O₂⁻ and cell death. CNCbl inhibited both Hcy and rotenone-induced mitochondrial O₂⁻ production. Similarly, HAEc challenged with paraquat showed a 1.5-fold increase in O₂⁻ levels and a 30% decrease in cell viability, both of which were prevented with CNCbl pretreatment. CNCbl also attenuated elevated O₂⁻ levels after exposure of cells to a Cu/Zn-SOD inhibitor. Our data suggest that Cbl acts as an efficient intracellular O₂⁻ scavenger.

xanthine oxidase and uncoupled nitric oxide synthase [20]. Exposing cells to Hcy also results in elevated levels of $O_2^−$ [21,22]. $O_2^−$ is involved in both physiological and pathological processes [23], with $O_2^−$ overproduction implicated in a range of inflammatory states such as rheumatoid arthritis, osteoarthritis, arteriosclerosis, and ischemia-reperfusion [24]. The toxicity of increased $O_2^−$ is evident in homozygous SOD2 knockout mice, which die within the first 3 weeks of age [25]. $O_2^−$ can inactivate a range of enzymes in addition to causing direct molecular damage by initiating lipoperoxidation, leading to the destruction of neurotransmitters and hormones, and DNA single-strand damage [20]. Moreover, $O_2^−$ can generate peroxynitrite via its reaction with nitric oxide and hydrogen peroxide via dismutation. From these species, stronger damaging oxidants can be generated, such as the carbonate, hydroxyl and nitrogen dioxide radicals, and oxoferryl complexes [26]. Therefore a tight control of $O_2^−$ is paramount to prevent the formation of secondary oxidants.

In this work we describe the protective effects of physiologically relevant concentrations of CNCbl against elevated intracellular $O_2^−$ levels induced by paraquat and l-Hcy and the associated cell injury in primary human aortic endothelial cells (HAEC). Both paraquat and l-Hcy induced elevated $O_2^−$ levels that paralleled cell death and which were prevented by pretreating the cells with CNCbl before the insult. Elevated $O_2^−$ levels were also observed in cells treated with the Cu/Zn-SOD inhibitor diethylthiocarbamate (DETC) [27] and were similarly attenuated by CNCbl pretreatment.

**Materials and methods**

**Synthesis of l- and d-Hcy**

L- or d-Homocysteine thiolactone (20 mg, 130 μmol) was dissolved in NaOH (5 N, 200 μl) and incubated at 37 °C for 10 min. The solution was chilled and neutralized with HCl (5 N, 200 μl). PBS was added to a total volume of 1 ml and the solution bubbled with N2 for 10 min [28]. The yield was typically >95%, determined by quantifying the reduced thiol groups by the Ellman assay [29].

**Cell culture**

Primary HAEC clones were a generous gift from Donald W. Jacobsen (Lerner Research Institute, The Cleveland Clinic). Each endothelial cell isolate was stored and passaged separately. HAEC were cultured in fibronectin-coated flasks in M199 supplemented with Lonza Bullet kit supplements for EBM-2 Endothelial Basal Medium in a humidified 95% air, 5% CO2 incubator at 37 °C. For experiments cells were seeded onto 96- or 24-well plates at a density of 12,000–20,000 cells/cm² and used up to passage 6.

**Intracellular Cbl content and Cbl uptake**

For Cbl-uptake experiments, preconfluent HAEC were incubated with 0.2 nM 57Co-CNCbl. Adherent cells were harvested at various time points up to 24 h and thoroughly washed with PBS. The intracellular Cbl uptake was determined by counting the cell-associated radioactivity. To measure total intracellular Cbl content, preconfluent HAEC were incubated with or without varying concentrations of CNCbl for 24 h, and intracellular Cbl content was determined by the SimulTRAC radioassay.

**Assessing ROS production**

Cells with or without CNCbl pretreatment (500 pM–10 μM) were incubated with l-Hcy (100 or 150 μM), H2O2 (50–200 μM), paraquat (1.5 μM), rotenone (5 μM), or culture medium alone. To assess general ROS production, cells were incubated with the oxidation-sensitive fluorescent probe dichlorofluorescein acetate (DCF; 3 μM) for the duration of the l-Hcy or H2O2 treatment. For the assessment of $O_2^−$ production, cells were incubated with the oxidative fluorescent probes dihydroethidium (DHE, 5 μM) or MitoSOX (5 μM) for 1 h subsequent to the l-Hcy, paraquat, or rotenone treatment. Fluorescence was quantified in a microplate reader (dichlorofluorescein DCF, $λ_{ex/em} = 420/520$; 2-hydroxyethidium, $λ_{ex/em} = 510/605$ nm; MitoSOX, $λ_{ex/em} = 510/580$ nm).

**Cell viability**

Cell viability was assessed with trypan blue staining or with the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay. For the MTT assay cells were incubated with thiazolyl blue tetrazolium (0.4 mg/ml) in M199 for 3 h at 37 °C. Mitochondrial-dependent tetrazolium reduction to formazan was measured by reading optical density at 540 nm.

**Cbl protection against $O_2^−$-generating insult l-Hcy, paraquat, or rotenone**

Preconfluent HAEC were incubated for 24 h in the absence or presence of CNCbl (500 pM–10 μM) before addition of l-Hcy (100 or 150 μM), paraquat (1.5 mM), or rotenone (5 μM). For some experiments SOD (3 μM) was added at the time of paraquat addition or apocynin (0.1 mM) was added 30 min before adding l-Hcy or paraquat. Cells were incubated for 24 h with l-Hcy, H2O2, or paraquat or for 1 h with rotenone. ROS and cell viability were assessed as described above.

**DETC**

Pre-confluent HAEC were incubated for 24 h in the absence or presence of CNCbl and then subjected to 10 mM DETC for 2 h. This concentration has been previously shown to inhibit Cu/Zn-SOD activity by up to 50% and to increase vascular $O_2^−$ [30].

**DNA and Cbl quantification**

Confluent cells were harvested in lysis buffer (50 mM Tris, pH 7.4, 0.5% Triton X-100) and DNA was quantified using the CyQuant cell proliferation kit (Roche). Cbl was quantified using the SimulTRAC radioassay for vitamin B12 and folate by MP Biomedicals (Orangeburg, NY, USA) according to the manufacturer’s specifications.

**Apoptosis measurement**

To detect apoptotic cell death, cells were seeded onto six-well plates and pretreated with or without CNCbl (10–100 nM) for 24 h. Cells were washed and then incubated in the absence or presence of l-Hcy for 18 h. Apoptosis was assessed using the Cell Death Detection ELISA Roche) according to the manufacturer’s specifications.

**General solution preparation**

Thiol solutions were prepared immediately before use and the concentrations were determined by the Ellman method [29]. A fresh solution of H2O2 was prepared before experiments and the concentration determined spectrophotometrically ($ε_{240 \text{ nm}} = 43.6 \text{ M}^{-1} \text{ cm}^{-1}$ [31]). The concentration of the stock solution of CNCbl was determined by the dicyanocobalamin test ($ε_{368 \text{ nm}} = 30.4 \text{ M}^{-1} \text{ cm}^{-1}$ [32]).

**Statistics**

All experiments were carried out using at least three separate cell clones. Results are expressed as means ± SEM. Statistical comparisons were carried out using ANOVA with the Bonferroni post hoc test.
Results

Cbl protects against elevated $\text{O}_2^-$ levels induced by Hcy exposure

Treatment of HAEC with varying concentrations of l-Hcy induced a concentration-dependent increase in ROS detected by increasing DCF fluorescence, a general probe for ROS. l-Hcy (100 μM) elicited a significant increase in ROS compared to control (Fig. 1). To verify that the ROS increase was an l-Hcy-specific effect, HAEC were incubated for 48 h with a range of thiols (glutathione, l-cysteine, d-Hcy, l-Hcy, and β-mercaptoethanol ([βME])) at 0.1 mM. Only l-Hcy elicited a significant increase in DCF fluorescence (Supplementary Fig. S1A), concomitant with a significant decrease in cell viability as measured using the MTT assay (Fig. S1B).

Before determining the effect of vitamin B12 (CNCbl) on l-Hcy-dependent ROS levels, we assessed the concentration- and time-dependent uptake of CNCbl by HAEC. Incubating HAEC with 57Co-labeled CNCbl (0.2 nM) induced a time-dependent increase in intracellular CNCbl (Fig. 2A). Increasing the CNCbl in the medium (0.1–10 μM unlabeled Cbl) led to higher intracellular Cbl levels after 24 h (Fig. 2B). A 24-h incubation time with CNCbl was selected as an appropriate time for all subsequent experiments.

Exposing HAEC to l-Hcy (150 μM) over 48 h induced a 1.25-fold increase in DCF fluorescence (Fig. 3A) that correlated with an ~25% decrease in cell viability (Fig. 3B). To assess the effects of CNCbl on the l-Hcy-dependent ROS production and the l-Hcy-dependent decrease in cell viability, HAEC were preincubated with increasing concentrations of CNCbl for 24 h before the cells were treated with l-Hcy (150 μM). To ensure that extracellular Cbl was not responsible for the Cbl effects on ROS, the cells were washed after Cbl treatment and the medium was replaced before further treatments. Preincubation of HAEC with CNCbl prevented the l-Hcy-dependent increase in ROS and decrease in cell viability in a concentration-dependent fashion (Fig. 3). CNCbl at 10 nM completely inhibited both the l-Hcy-dependent ROS increase ($p<0.05$) and the l-Hcy-dependent decrease in cell viability ($p<0.05$). l-Hcy (150 μM) treatment of cells over a 24-h period resulted in a ~20% decrease in cell viability; hence, subsequent experiments were conducted using a 24-h l-Hcy treatment protocol, unless otherwise stated.

Exposing cells to l-Hcy is reported to increase intracellular $\text{O}_2^-$ levels [21,22]. To determine if $\text{O}_2^-$ is indeed generated in our system, $\text{O}_2^-$ levels after exposure to l-Hcy were assessed using the $\text{O}_2^-$ specific probe DHE, which upon reacting with $\text{O}_2^-$ yields the fluorescent product 2-hydroxyethidium. Incubation of HAEC with l-Hcy (150 μM) for 24 h induced a 1.6-fold increase in hydroxyethidium fluorescence (Fig. 4 and Supplementary Figs. S2 and S3). This increase was completely inhibited by preincubation of the cells with 10 nM CNCbl ($p<0.05$), the antioxidant apocynin (0.1 mM), or SOD itself (3 μM) (Fig. 4 and Supplementary Figs. S2 and S3).

Cbl protects against elevated mitochondrial $\text{O}_2^-$ levels

To investigate the subcellular localization of the l-Hcy-induced increase in $\text{O}_2^-$, cells were assayed with MitoSOX, a mitochondrial-specific $\text{O}_2^-$ probe. Incubation of HAEC with l-Hcy (150 μM) for 24 h elicited a moderate but significant increase in MitoSOX fluorescence, which was completely inhibited by preincubation of the cells with CNCbl (50 nM) (Fig. 5). Moreover, treatment of HAEC with the mitochondrial electron transport chain inhibitor rotenone (5 μM) induced an increase in mitochondrial $\text{O}_2^-$ that was also significantly inhibited by preincubation with CNCbl (100 nM) (Fig. 5 and Supplementary Fig. S4).

Cbl protects against elevated $\text{O}_2^-$ levels induced by paraquat

To assess the ability of CNCbl to protect against a direct source of $\text{O}_2^-$, HAEC were exposed to paraquat (1.5 mM, 24 h), a well-established $\text{O}_2^-$ source [33]. Paraquat induced a 1.5-fold increase in $\text{O}_2^-$ production measured by hydroxyethidium fluorescence, which was prevented by
CNCbl pretreatment (10 nM), apocynin (0.1 mM), and SOD (3 μM) (Fig. 6A). The paraquat-induced increase in oxidative stress correlated with a 30% decrease in cell viability (Fig. 6B). Preincubation with CNCbl for 24 h or treatment with apocynin (0.1 mM) or SOD (3 μM) protected HAEC against the O2•−-dependent decrease in cell viability (Fig. 6B).

Cbl attenuates elevated O2•− levels resulting from Cu/Zn-SOD inhibition

To explore the possibility that Cbl can act as a second line of defense when O2•− production overwhelms the SOD capacity, we inhibited Cu/Zn-SOD by treating HAEC with DETC (10 mM) for 2 h with or without CNCbl pretreatment. Incubation with DETC elicited an increase in DHE fluorescence indicative of higher intracellular O2•− levels. Pretreatment with CNCbl (100 nM) significantly reduced the DETC-induced DHE fluorescence (Fig. 7), providing support for CNCbl’s ability to scavenge O2•− in SOD-compromised cells.

Cbl protects against Hcy-dependent increase in apoptotic cell death

Exposing HAEC to l-Hcy (150 μM) for 24 h caused a significant decrease in cell viability as measured by the MTT assay (Fig. 8A). Because the MTT assay is a measure of mitochondrial function and metabolic activity, cell death was directly assessed by trypan blue staining, which corresponded to the MTT results (Fig. 8B). Finally, to characterize the l-Hcy-induced cell death, apoptosis was assessed by measuring cytosolic fragmented DNA with an ELISA-based cell death assay (Roche). HAEC showed a significant increase in apoptotic cell death in response to l-Hcy (150 μM) for 18 h (Fig. 9). Because both CNCbl and apocynin prevented the l-Hcy-induced decrease in cell viability, as measured by the MTT assay (Fig. 8A), and the increase in cell death, as measured by trypan blue staining (Fig. 8B) or ELISA (Fig. 9), it appears that CNCbl provides protection against apoptosis.

Discussion

Vitamin B12 is an essential micronutrient required for one-carbon metabolism and branched-amino-acid catabolism. Recent studies in our laboratories showed that Cbl(II) can directly scavenge O2•− to form aquacobalamin (and hydrogen peroxide) extremely rapidly, at a rate approaching that of SOD-catalyzed dismutation (7×10^8 vs 2×10^9 M−1 s−1) [6]. Substantial free (non-protein-bound)
intracellular Cbl can be achieved with supplementation [36–39]. Upon entering cells the cobalt(III) center of Cbl is reduced to cobalt(II) (= Cbl(II)) before binding to the B12-dependent enzymes [40]. The ability of cells to re-reduce free aquacobalamin to Cbl(II) ("aquacobalamin reductase activity") is well established [41–46], therefore providing the theoretical basis for Cbl-mediated catalytic O$_2^•−$ scavenging. This led us to speculate that Cbl might protect cells from oxidative stress by efficient O$_2^•−$ scavenging.

In our studies, intracellular O$_2^•−$ was generated by treating HAEC with paraquat, and the ability of CNCbl to protect cells against damage was assessed. CNCbl at nanomolar concentrations could prevent the increase in O$_2^•−$ levels and the associated reduction in cell viability (Fig. 6). The inhibitory effects of CNCbl were comparable to those observed with apocynin or SOD itself (Fig. 6).

The inhibition of Cu/Zn-SOD with DETC treatment also elevated cytosolic O$_2^•−$ levels. DETC-treated cells were round and loosely attached compared to spindle-shaped control cells, demonstrating the dramatic effect of inhibiting Cu/Zn-SOD in HAEC. Pretreating HAEC with CNCbl (100 nM) attenuated the DETC-induced increase in O$_2^•−$ and also partially reverted the altered cell morphology, which further supports the direct effect of Cbl on intracellular O$_2^•−$.

**Fig. 6.** Effect of Cbl on paraquat-induced O$_2^•−$ levels and cell death. HAEC were incubated in the absence or in the presence of varying concentrations of CNCbl for 24 h before paraquat (1.5 mM) treatment. DHE (5 μM) was added for the final 1 h of treatment. Also shown are the effects of SOD (3 μM) and apocynin (AC; 0.1 mM) on the paraquat-induced increase in O$_2^•−$ and cell death. (A) O$_2^•−$ measured as hydroxyethidium fluorescence ($\lambda_{ex}$/$\lambda_{em}$ = 520/605 nm) compared to untreated cells. (B) Cell viability was assessed with the MTT assay. Data expressed as the mean±SEM; $N=3$; *p<0.05 compared to control, #p<0.05 compared to paraquat alone.

**Fig. 8.** Cbl protection against L-Hcy-induced cell death. Preconfluent HAEC were incubated in the presence or absence of 10 or 50 nM CNCbl for 24 h before addition of 150 μM L-Hcy for 24 h in the presence or absence of apocynin (0.1 mM). (A) Cell viability by the MTT assay. Data are expressed as the mean±SEM; $N=4$. (B) Trypan blue uptake. Data are expressed as the mean±SEM; $N=3$. *p<0.05 with respect to control cells not exposed to L-Hcy; †p<0.05 with respect to L-Hcy-treated HAEC.
L-Hcy metabolism alone and that Cbl can act to protect against oxidative stress. However, our experiments indicate that Cbl shows effects are perhaps not surprising, given the cofactor role of Cbl in Hcy metabolism. Moreover, elevated Hcy is associated with vascular oxidative stress. Normally, plasma Hcy levels are maintained below 12 μM; however, in clinical hyperhomocysteinemia, Hcy levels can exceed 100 μM in severe instances [47]. To ensure a universal response among our individual HAEC clones, our experiments used a high but still pathophysiological range of Hcy concentrations (100–150 μM), which increased O2− levels and resulted in an associated loss of cell viability. As with paraquat, these effects were completely inhibited by pretreating HAEC with CNCbl (10 nM) or by treating the cells with apocynin or SOD itself.

The increase in L-Hcy-induced cell death correlated with increased apoptotic cell death. L-Hcy induces apoptosis in human bone marrow stromal cells [48], human umbilical vein endothelial cells [49,50], and endothelial progenitor cells [51]. It also inhibits growth [52] and reduces cell viability in HAEC [53]. Our results are consistent with previous studies in other endothelial cell lines; however, to our knowledge, we are the first to show L-Hcy induced apoptotic cell death in primary cultures of HAEC. L-Hcy-induced apoptosis was prevented by apocynin or by pretreating HAEC with CNCbl (50 nM).

The protective effects of Cbl against L-Hcy-induced oxidative stress are perhaps not surprising, given the cofactor role of Cbl in Hcy metabolism. However, our experiments indicate that Cbl shows effects against O2− generated in response to a variety of insults apart from Hcy (i.e., paraquat, rotenone, DETC). Such results indicate that Cbl protects against Hcy-mediated oxidative stress may not be due to increasing Hcy metabolism alone and that Cbl can act to protect against oxidative stress in a general manner. These data, combined with our previous in vitro studies showing a direct and fast reaction between Cbl(II) and O2−, strongly implicate Cbl as an intracellular O2− scavenger. However, in the case of Hcy, we cannot rule out the involvement of other mechanisms independent of O2− scavenging in the CNCbl-mediated protective effects.

An important finding from our studies is the effectiveness of CNCbl against mitochondrial oxidative stress. Oxidative stress-associated mitochondrial dysfunction is a common feature in cardiovascular pathologies [54,55] and there is considerable interest in developing mitochondrial-specific antioxidants [55,56]. Hcy increases mitochondrial oxidative stress in brain [57] and cardiac myocytes [58]. Cbl is present in the mitochondria (Cbl-dependent l-methylmalonyl-CoA mutase is a mitochondrial enzyme) and ~80% of Cbl is in its Cbl(II) form [2]. In endothelial cells the mitochondrial AdoCbl concentration is fourfold higher than the cytosolic MeCbl concentration [59] and a substantial fraction of mitochondrial Cbl is not protein bound [60]. In our studies, CNCbl treatment effectively inhibited the generation of mitochondrial O2− by Hcy or rotenone treatment (Fig. 5).

DHE remains one of the most widely used probes for detection of O2− in live cells, although 2-hydroxyethidium, the specific reaction product between DHE and O2−, is not the only DHE fluorescent oxidation product. Ethidium, a one-electron oxidation product of DHE, has an emission spectrum with a 45% overlap with that of 2-hydroxyethidium [61]. The same applies for the mitochondria-targeted ethidium derivative MitoSOX and its oxidation products [61]. Therefore, the specificity of DHE for detecting O2− levels has been questioned. However, our conclusions are not solely based on the effect of Cbl on DHE or MitoSOX oxidation. The oxidative-stress-inducing insults used in our studies have been shown to increase O2− levels in previous studies using lucigenin chemiluminescence or EPR [21,22,30,62,63], and these data correlate well with an increase in DHE-derived fluorescence. Thus, because O2− is the predominant ROS produced in these systems, the Cbl effect was mimicked by SOD, and our previous studies show that Cbl reacts very rapidly with O2−, we conclude that the Cbl-dependent decrease in DHE fluorescence is due to a direct Cbl-mediated O2− scavenging mechanism.

It is likely that Cbl has biological roles beyond its ability to act as a cofactor for the two mammalian B12-dependent enzyme reactions (reviewed by Solomon [19]). Cbl supplementation can be beneficial in treating a range of inflammatory and viral-based diseases associated with oxidative stress [10–16] and also modulates the immune response [64,65]. Moreover, high doses of Cbl have been used to treat pernicious anemia for decades with no apparent toxicity [66]. Cbl therapy normalizes levels of TNF-α and epidermal growth factor in Cbl-deficient patients [64], by a mechanism(s) that is currently unclear. Thus, there are intriguing clinical implications for our observed association between Cbl and intracellular O2− levels. Our results support the hypothesis that Cbl can act as a second line of defense when O2− production overwhelms the SOD protection system. This perhaps accounts for significantly increased oxidative damage markers in patients with inherited disorders of intracellular Cbl metabolism [67].

Our data show that physiologically relevant concentrations (up to 10−7 M are achievable in plasma [34,35]) of CNCbl (the common form of Cbl in vitamin supplements) effectively protect against increased intracellular levels of O2− both in the cytosol and in the mitochondria, resulting in a concomitant reduction in cell death. Importantly, these effects were found to be independent of Hcy metabolism. These results, combined with the in vitro kinetic data demonstrating that Cbl(II) efficiently scavenges O2− [6], suggest that direct scavenging of O2− by Cbl is an important mechanism by which Cbl protects against intracellular oxidative stress. Our results have important implications both in regard to the high percentage of the elderly who are B12 deficient and in the treatment of chronic inflammatory diseases associated with oxidative stress. These results encourage further studies with animal models to test the efficacy of Cbl as a O2− scavenger in vivo.
